Summary  Chestnut astringent skin (CAS) extract inhibited pancreatic α-amylase and intestinal α-glucosidase in a concentration-dependent manner with the 50% inhibition concentration (IC50) for amylase, maltase and sucrase being 7.5, 650 and 390 μg/mL, respectively. We have investigated the effect of CAS extract on carbohydrate absorption in normal rats. Oral administration of CAS extract to rats fed cornstarch (2 g/kg body weight) significantly suppressed the increase of blood glucose levels and the area under the curve (AUC). Administration of CAS extract to rats fed maltose or sucrase delayed the increase of blood glucose level and slightly suppressed AUC, but not significantly. Administration of CAS extract to rats fed glucose did not affect the increase in blood glucose level or AUC. Similar results were observed with type-2 diabetic model rats (GK/ob). To test the effect of CAS extract on diabetes, type 2 diabetic model mice (db/db mice) were fed a standard laboratory diet containing 1 or 2% CAS extract. CAS extract prevented increases in body weight and fasting blood glucose concentration. These data suggest that CAS extract has an anti-diabetic function in type 2 diabetic mice that mainly functions through inhibition of α-amylase.

Key Words  chestnut astringent skin, amylose inhibitor, blood glucose, oral carbohydrate tolerance test, db/db mice

In mammals, dietary carbohydrate digestion is mediated by digestive enzymes such as amylase and α-glucosidase. α-Amylase is a key enzyme in dietary carbohydrate absorption catalyzing the first step in carbohydrate digestion by hydrolyzing the α-1,4 glucoside linkages of polysaccharides such as starch (transforming starch to oligosaccharides). The oligosaccharides are further hydrolyzed by α-glucosidas such as maltase and sucrase, which are located in the brush-border surface membrane of intestinal cells. Maltase hydrolyzes maltose and sucrase hydrolyzes sucrase. After these steps the resulting product, glucose, is absorbed into the small intestine and the blood glucose concentration increases. If these enzymes are inhibited, dietary carbohydrate absorption is also inhibited and the subsequent increase in blood glucose concentration is inhibited. Thus, many inhibitors of carbohydrate digestion enzymes have been marketed for the regulation of blood glucose concentration, for example, acarbose, voglibose and 0.19 wheat protein (1–4). Acarbose and voglibose are strong α-glucosidase inhibitors and typical therapeutic agents used to control post-prandial glucose concentration and are thus used in treatment of type 2 diabetes (5, 6). The wheat protein is a homodimer of 26.6 kDa and is an amylase inhibitor (7, 8), and is used as a functional food to both prevent and treat diabetes.

We previously reported that chestnut astringent skin (CAS) extract was a strong inhibitor of α-amylase and reported that it could attenuate the rapid increase in blood glucose following consumption of a carbohydrate-containing meal by delaying or blocking absorption of carbohydrate (9). We also suggested that an active component(s) of the CAS extract might be a polyphenol. In this study, we have examined the mechanism of the inhibitory action of CAS extract on carbohydrate absorption. We have also examined the effect of CAS extract on diabetes in db/db mice.

MATERIALS AND METHODS

Materials.  CAS was obtained form Chuon Co. Ltd. (Matsuyama, Japan) and extracted with aqueous ethanol. One hundred grams of CAS were added to 200 mL of 75% aqueous ethanol, followed by stirring at 37°C for 12 h. The mixture was filtered and the filtrate concentrated and lyophilized. α-Amylase from porcine pancreas was obtained from Sigma-Aldrich Japan (Tokyo, Japan). An enzyme solution of α-glucosidases was prepared from rat small intestine (10, 11).

Enzyme assay methods.  α-Amylase activity was determined by measuring the reducing power of released oligosaccharide from soluble starch by the method of Miller (12) with minor modifications (9). Maltase and sucrase activities were determined using maltose and sucrase as substrates, and the glucose pro-

duced in the reaction was measured with a commercial assay kit (Glucose C II-test, Wako Pure Chemical Industries, Ltd., Osaka, Japan) (10, 11).

Oral carbohydrate tolerance test in rats. The experimental animal protocol was approved by the Animal Study Committee of Ehime University. Male Crl:Wistar rats (150 g, 6 wk old) were obtained from CLEA Japan, Inc. (Tokyo, Japan) and housed in a temperature (23°C)-and humidity (60%)-controlled room set to a 12/12 h light/dark cycle. After the animals were given a standard laboratory diet (MF, Oriental Yeast Co., Ltd., Osaka, Japan) and water ad libitum for 1 wk, they were starved overnight (15 h) and divided into two groups. The test group received 2 mL of carbohydrate solution (2 g/kg body weight) containing 1 mL of CAS extract powder solution while the control group received carbohydrate solution and 1 mL of water. After administration, blood samples were collected from the tail vein or artery at regular intervals. Blood glucose was measured using a blood glucose test meter, GLUCO CARD (Arkray Inc., Kyoto, Japan). After a 1-wk interval, the test and control groups were switched and the experiment was repeated. Type 2 diabetic model rats (male GK/Jcl, 300 g, 14 wk) were obtained from CLEA Japan, Inc. After 1 wk feeding a standard laboratory diet, they were starved overnight (15 h), and subjected to the carbohydrate tolerance test as described above.

Effect of CAS extract on type II diabetic model mice. Type 2 diabetic model mice (male +Lepr-db/+Lepr-db/Jcl, db/db mice, 6 wk old) were obtained from CLEA Japan, Inc. and housed in a temperature (23°C)-and humidity (60%)-controlled room set to a 12 h/12 h light/dark cycle. After the animals were given a standard laboratory diet (MF, Oriental Yeast Co., Ltd.) and water ad libitum for 1 wk, they were divided into three groups matched for body weight (each n = 10). One group, the control diet group, was fed the standard laboratory diet (water 7.7%, protein 23.6%, fat 5.3%, ash 6.1%, dietary fiber 2.9%, soluble non-nitrogen compound 54.4%, 360 kcal/100 g) The other two groups, the CAS extract groups, were fed the standard laboratory diet containing different amounts of CAS extract (1 and 2%). They were given free access to food and water, and body weight gain and food consumption were measured weekly. For determination of fasting blood glucose concentration, mice were starved overnight (15 h) and blood samples were collected from the tail vein or artery. Blood glucose was measured using a blood glucose test meter. The experiments were performed at 1-wk intervals. After 8 wk of feeding on the indicated diet, blood and tissues were collected. Plasma and liver lipids were measured as described previously (13).

Statistical analysis. Results are expressed as the mean±SE. The statistical significance of differences with and without (control) CAS extract was assessed using Student’s t-test.

RESULTS

CAS extract powder is a dark brown powder containing 25.7% polyphenolic material (9) which inhibits α-amylase and intestinal α-glucosidase activities in a concentration-dependent manner (Fig. 1). A concentration of 7.5 μg/mL was determined to result in 50% inhibition of α-amylase. However, the IC50 values of CAS extract for α-glucosidase were 50 to 80 times higher than that for α-amylase: 650 and 340 μg/mL towards maltase and sucrase activity, respectively. The IC50 values of CAS extract powder for α-amylase did not change at 40°C for 6 mo (data not shown). The IC50 value of CAS extract also did not change when CAS extract water suspension (10 mg/mL) was incubated at 100°C for 1 h. However, the IC50 value of CAS extract suspension was increased about 2.8-times by incubation at 120°C for 30 min.

We examined whether the enzyme inhibition by CAS extract observed in vitro could exert an inhibitory effect on carbohydrate absorption in vivo. In normal rats blood glucose levels increased from a baseline of 47.6±1.84 mg/dL at 0 min to a peak of 95.9±2.30 mg/dL (increased blood glucose value 49.3±3.09 mg/dL) at 60 min after starch administration (2 g/kg body weight). The rise in blood glucose was suppressed significantly when CAS extract (100 mg/kg body weight) was given with starch (Fig. 2A-1). The area under the curve (AUC0-180min) was calculated geometrically, accounting for area under the curve of incremental blood glucose level up to 180 min. AUC0-180min for CAS extract administration was also found to decrease significantly compared to administration of starch alone (Fig. 2A-2). Figure 2B shows maltase administration. In normal rats blood glucose levels increased from a baseline of 46.7±2.14 mg/dL at 0 min to a peak of
110.3±4.09 mg/dl (increased blood glucose value 63.6±2.96 mg/dl) at 60 min after maltose administration (2 g/kg body weight). At 60 min the rise in blood glucose was significantly suppressed when CAS extract (100 mg/kg body weight) was given with maltose while the level was significantly increased at 120 min (Fig. 2B-1). AUC0–180 min for CAS extract administration was slightly decreased, but not significantly, compared to administration of maltose alone (Fig. 2B-2). Similar results were observed with sucrose administration (Fig. 2C). Blood glucose levels increased from a baseline of 53.5±2.78 mg/dl at 0 min to a peak of 101.8±3.70 mg/dl (increased blood glucose value 48.3±6.12 mg/dl) at 60 min after sucrose administration (2 g/kg body weight). The rise in blood glucose was suppressed at 60 min when CAS extract (100 mg/kg body weight) was given while the level was increased at 120 min (Fig. 2C-1). AUC0–180 min for CAS extract administration was slightly decreased, but not significantly compared to administration of sucrose alone (Fig. 2C-2). The rise in blood glucose and AUC0–180 min after glucose administration (2 g/kg body weight) was unaffected by administration of CAS extract (Fig. 2D). Similar results were observed in the type-2 diabetic model rats (GK/jcl) (Fig. 3). Fasting blood glucose levels in diabetic model rats were high 96±8.1 mg/dl, and blood glucose levels increased to a peak of 406±19.4 mg/dl (increased blood glucose value 309±18.1 mg/dl) at 60 min after
starch administration (2 g/kg body weight). The rise in blood glucose was suppressed significantly when CAS extract (300 mg/kg body weight) was given with starch (Fig. 3A). AUC_{0-180 min} for CAS extract administration was found to decrease significantly compared to that with administration of starch alone (data not shown). With maltose administration (2 g/kg body weight), blood glucose levels increased from a baseline of 99.8±6.7 mg/dL at 0 min to a peak of 459±27.9 mg/dL (increased blood glucose value 359±24.9 mg/dL) at 60 min. At 60 min the rise in blood glucose was suppressed when CAS extract (300 mg/kg body weight) was given with maltose while the level was significantly increased at 120 min (Fig. 3B). The rise in blood glucose however was not much changed after glucose administration (2 g/kg body weight) upon inclusion of CAS (Fig. 3C).

We examined the effect of CAS extract on body weight and fasting blood glucose levels in type 2 diabetic model mice (db/db mice). The results show that CAS extract suppressed increases in body weight (Fig. 4A). The diet containing 2% CAS extract significantly suppressed the body weight during weeks 3 to 6 of the experimental period and the 1% CAS extract diet also suppressed the body weight at the 3rd week of the experimental period. The energy intake per mouse did not differ much during the whole experimental period regardless of whether CAS was included in the diet (Fig 4B). The fasting blood glucose concentration of db/db mice was high (150±9.1 mg/dL) when the experiment began (7 wk of age), and increased to 457±34.2 mg/dL 8 wk into the experimental period (15 wk of age). CAS extract concentration-dependently lowered the fasting blood glucose level compared to the control group (Fig. 5). The 2% CAS extract diet significantly lowered the fasting blood glucose level over the whole experimental period. The CAS extract diet (2%) also significantly suppressed the wet weight of epididymal adipose tissue compared to the control group (control: 2.30±0.09 g, 1% CAS extract: 2.23±0.10 g, 2% CAS extract: 2.05±0.07 g). Liver weight and plasma lipid concentration were similar for diets with and without CAS extract (data not shown). Liver lipid concentrations were also similar for diets both with and without CAS extract (data not shown).

**DISCUSSION**

Chestnut is a deciduous timber tree of the genus *Castanea*, in the beech family and is cultivated over a large area of Japan. We examined the effect of chestnut extracts on α-amylase activity. Chestnut parts such as bark, leaf, bur-spine, shell and astringent skin were extracted with ethanol-containing water and the amylase inhibitory activities assayed. All extracts inhibited the α-amylase activity (data not shown). In particular, shell and astringent skin extract strongly inhibited α-amylase activity. Shell and astringent skin of chestnut are generated in large quantities as waste products during astringent skin-free nut processing. Astringent skin is recognized as an edible fraction but shell is not. Therefore, we used astringent skin as a candidate safe and inexpensive functional food material.

Diabetes is a disease in which the amount of blood glucose is too high because the body cannot use glucose
properly. There are two main types of diabetes, Type 1 and Type 2. Type 1 diabetes is insulin dependent with patients unable to produce insulin. Type 2 diabetes is non-insulin dependent with patients able to make some insulin, but where cells become resistant to insulin. Diabetes is a major worldwide public health problem with the number of patients increasing greatly in the last 50 years in both developed and developing nations (14). In Japan, about 8.2 million people are diabetic patients and about 10.5 million people are pre-diabetic patients (from the actual conditional report of 2006 from the Ministry of Health, Labor and Welfare of Japan). For diabetic patients, maintenance of healthy blood glucose levels is important and blood glucose concentration is greatly affected by dietary carbohydrates. Recent studies suggest that postprandial hyperglycemia is an important contributing factor to the development of atherosclerosis and cardiovascular disease (15–17). Postprandial hyperglycemia induces adhesion molecules and coagulation factors in vascular wall cells via oxidative stress generation and is thus involved in the pathogenesis of endothelial dysfunction and atherosclerosis. Therefore, control of postprandial plasma glucose levels is important and various α-glucosidase or α-amylase inhibitors have been used to inhibit excess energy supply, to control blood glucose levels and to prevent or treat obesity and diabetes (18–20). Previously, we reported that CAS extract retarded absorption of carbohydrate and reduced postprandial hyperglycemia in rats and humans (9).

In vitro, CAS extract strongly inhibits α-amylase activity, with the IC₅₀ value for α-amylase being about 50 to 80 times lower than that for α-glucosidases such as maltase and sucrase (Fig. 1). These results were reflected in the in vivo results (Figs. 2 and 3). Thus, CAS extract significantly suppressed the rise in blood glucose level and total carbohydrate absorption after starch administration. Upon administration of maltose or sucrose, although CAS extract delayed the rise in blood glucose level it did not suppress total carbohydrate absorption. Furthermore, CAS extract did not affect the rise in blood glucose level or total carbohydrate absorption upon administration of glucose. These results suggest that the suppression of carbohydrate absorption by CAS extract mainly results from α-amylase inhibition.

The db/db mouse is a mutant leptin receptor inbred strain maintained on a BL/6 background. It is a genetic model of type 2 diabetes that displays many of the characteristics of the human disease including hyperglycemia, insulin resistance and obesity (21–23). The body weight of db/db mice increased upon overeating with animals reaching 45.8 ± 0.98 g at 15 wk of age, a value which is almost 1.5-fold the weight of control mice (normal 57/BL mice, 29.1 ± 0.73 g) (13). CAS extract prevented the increase in body weight and adipose tissue weight of mice without a decrease in the food intake (Fig. 4). CAS extract also prevented the increase in the fasting blood glucose level (Fig. 5). Previously we reported that CAS extract retarded absorption of carbohydrate and reduced postprandial hyperglycemia in diabetic rats and humans (9). These results suggest that CAS extract exerts an anti-diabetic effect by inhibiting α-amylase, retards carbohydrate absorption and reduces post-prandial hyperglycemia. Therefore, CAS extract is a strong candidate as an agent that inhibits carbohydrate absorption.
