The hydrothermal-electrochemical method is best suited for producing homogeneous apatite coatings on electro-conductive materials with complicated shape, such as the mesh. This study was undertaken to examine the effect of the apatite coating prepared by this coating method on cell adhesion, proliferation, and differentiation of MC3T3-E1 cells in culture. The cells attached and spread well on the electrochemically deposited apatite on titanium mesh. The number of cells that adhered on the deposited apatite on titanium mesh was much greater than that on the surface without coating, and that it also depended on the morphology of apatites. When alkaline phosphatase activity as well as collagen and osteocalcin of the extracellular matrix were measured, the electrochemically apatite-coated titanium mesh showed higher measurement values than the titanium mesh without coating. These results suggested that the apatite-coated titanium mesh prepared by hydrothermal-electrochemical method has excellent biocompatibility.

Key words: Apatite, Biocompatibility, Biomaterials

INTRODUCTION

Polymers or copolymer acids, calcium phosphates, and collagen have been employed as scaffold materials, which are a creative development of osteoinductive bone graft substitutes. A disadvantage of these materials is that they are not very strong and can transform easily1). Titanium mesh has been used in plastic surgery and oral surgery, because it has excellent mechanical properties in terms of stiffness and plasticity, bone compatibility, and ease of use during surgery2). For example, the use of titanium mesh was rekindled by von Arx et al. in the TIME technique, whereby microtitanium augmentation mesh was specifically designed for ridge augmentation3).

An additional advantage of titanium is that it can be used as a substrate for calcium phosphate coating—which has been described to have a positive effect on bone formation. It is generally assumed that calcium phosphate coatings enhance bone formation. In fact, Vehof et al.4) showed that calcium phosphate-coated titanium mesh facilitated excellent bone generation, whereby this coating was prepared by magnetron sputtering.

In terms of coating method, a number of coating techniques are available: plasma spray5,6), ion-beam-assisted deposition7), and radiofrequency magnetron sputtering8). However, regarding the long-term performance of coatings obtained via these methods, some drawbacks have been noticed: poor mechanical properties and non-homogeneity9). We have been studying apatite coating on titanium by hydrothermal-electrochemical deposition10−18). The advantages of this coating method are that it easily produces a homogeneous apatite coating on electro-conductive materials with complicated shape such as mesh19,20), requires a lower processing temperature, and entails only simple and inexpensive preparation method. Further, it is known that apatite coatings can promote bone ingrowths, enhance direct bone contact15), as well as facilitate differentiation of bone marrow stromal cells along the osteogenic lineage22).

The purpose of the present study was to investigate the effect of electrochemically deposited apatite on cell adhesion, proliferation, and differentiation of MC3T3-E1 cells in culture, and to discuss the biocompatibility of titanium mesh with apatite coating.

MATERIALS AND METHODS

Sample preparation

Grid 80 mesh woven with 120-μm diameter titanium fibers (458080, Nilaco, Tokyo, Japan) was cut to 10×10 mm squares. Surface area of the 10-mm square titanium mesh was derived from the dimensional parameters of the mesh. Apatites were formed on this titanium mesh using a hydrothermal-electrochemical method. The electrolyte was prepared by dissolving 137.8 mM of NaCl, 1.67 mM of K2HPO4, and 2.5 mM of CaCl2·2H2O in distilled water. The solution was buffered to pH 7.2 at room temperature with 50 mM tris(hydroxymethyl)-aminomethane [(CH2OH)2CNH2]
and an adequate amount of HCl. The autoclave contained 1 L of the electrolyte in a Pyrex beaker and was sealed by bolting under a Teflon gasket. The electrolyte was then heated and maintained at 90, 100, and 150°C in a stainless steel autoclave with two electrodes. Anode, the counter electrode, was a 20 × 20 × 0.5 mm platinum plate. A constant direct current was loaded at 12 mA/cm² to the #80 titanium meshes for one hour. After constant current loading, the titanium mesh as cathode was rinsed with distilled water and dried at 37°C. More details about the hydrothermal-electrochemical deposition of apatite were discussed in our previous papers.²¹²²

The deposits were then characterized by scanning electron microscopy (SEM; JSM-5510, JEOL, Tokyo, Japan), X-ray diffractionometry (XRD; RINT 2500, Rigaku, Tokyo, Japan), and energy dispersive X-ray spectrometry (EDS; JED-2300, JEOL, Tokyo, Japan).

**Cell cultures**

Mouse osteoblast-like cells (MC3T3-E1) were cultured at 37°C in a humidified atmosphere of 5% CO₂ in air. The cell suspension was cultured in minimum essential medium alpha modification (a-MEM; Invitrogen, Groningen, Netherlands) with 10% fetal bovine serum (PBS; Moregate Biotech, Bulimba, Australia) supplemented with 2 mM L-glutamine, 70 μg/ml of benzyl penicillin potassium, and 100 μg/ml of streptomycin sulfate. To induce spontaneous differentiation, 10 mM β-glycerophosphate as well as 50 μg/ml ascorbic acid were added to the culture medium. To evaluate the effect of apatite coating on cell attachment in each condition, 1 × 10⁴ cells/cm² was plated onto the deposited apatite on the titanium mesh (0.5 × 0.5 cm) which had been placed into individual wells of a 24-well plate. Cells with the same density were also cultured on a 24-well plate, which was used as the control group.

**Cell attachment and proliferation**

Cells grown on the apatite coating on titanium mesh after three days were fixed in 2.5% glutaraldehyde with 0.1 M sodium cacodylate buffer (pH 7.4 and 4°C) for one hour and postfixed for 30 minutes with 1% osmium tetroxide in 0.1 M cacodylate buffer. After dehydration in graded ethanolys, specimens were transferred into t-butyl alcohol and freeze-dried. Specimens were sputter-coated with gold, and cell morphology was observed by SEM.

Cell proliferation was measured at 4, 8, and 12 days. Cells in each well were counted using a kit (Cell-counting Kit-8, Dojindo Laboratories, Kumamoto, Japan). The counting technique employed a tetrazolium salt that produced a highly water-soluble formazan dye. After one hour of incubation with reagent according to the manufacturer's instructions, relative cell number was determined by measuring light absorbance at a wavelength of 450 nm by formazan dye product in the cultures.

**Alkaline phosphatase (ALP) activity**

For quantitative analysis of ALP activity, cells were washed twice with phosphate-buffered saline (PBS; Nissui Pharmaceutical, Tokyo, Japan) and sonicated for 10 seconds with lysis buffer (1.5 M Tris-HCl at pH 9.2, 1 mM ZnCl₂, 1 mM MgCl₂·6H₂O, and 1% Triton X-100). ALP activity in this lysate was measured at 37°C for 15 minutes in 7.5 mM alkaline buffer solution (Sigma 221, Sigma, St. Louis, MO, USA) with p-nitrophenol phosphate (Sigma 104) as a substrate. The relative amount of p-nitrophenol was estimated by measuring light absorbance at a wavelength of 405 nm. Known dilutions of p-nitrophenol solution (Sigma 104-1) were used as a standard. ALP activity was expressed relative to protein content of samples as determined using a DC protein assay kit (Bio-Rad Laboratories, Hercules, CA, USA).

**Collagen assay**

Collagen was determined by a soluble collagen assay kit (Biodyne Science, Northern Ireland). Standards (soluble type I collagen), test samples, and blanks were added into microcentrifuge tubes, followed by 1 ml dye reagent. All the tubes were capped and placed in a mechanical shaker for 30 minutes. Next, the tubes were transferred to a microcentrifuge and spun at 10,000×g for 10 minutes. Unbound dye solution was removed by carefully inverting and draining the tubes, and then 1 ml of an alkaline reagent was added. Aliquots of each sample were transferred from the tubes to the wells of a 96-well plate. Optical density of each well was determined using a microplate reader set to 540 nm. Sample values were determined by comparison with a standard curve.

**Osteocalcin assay**

Osteocalcin was determined by mouse osteocalcin EIA KIT (Biomedical Technologies Inc., MA, USA) according to the manufacturer's instructions. Standards, test samples, and blanks were added to individual wells, followed by biotinylated antibody, and incubated at 4°C for 24 hours. After washing, peroxidase conjugate was added to each well and incubated in the dark at room temperature. Light absorbance was measured at 450 nm wavelength.

**Statistical analysis**

For statistical analysis, one-way ANOVA and post-hoc Fisher's PLSD test were performed.

**RESULTS**

**Apatite structure**

After hydrothermal-electrochemical coating, the mesh was homogeneously covered with white deposits (Fig.
BIOMETIBILITY OF APATITE-COATED TITANIUM MESH

1). SEM photographs showed that the deposits were homogeneously formed on the surface of the titanium fibers (Fig. 2). Plate-like deposits were formed on the titanium mesh at 90°C. Needle-like and plate-like deposits were formed at 100°C, whereas only needle-like deposits were formed at 150°C. Thickness of the thin plates at 90°C was about 0.1 μm and the width was 30-80 μm. At 100°C, the needle-like deposits were 0.5-1 μm in width and about 7 μm in length. At 150°C, the needle-like deposits were 2-7 μm in width and 60-90 μm in length. Size of the needle-like deposits increased with the electrolyte temperature. Furthermore, most of the needles grew perpendicular to the surface of the mesh fiber, and their sharp edges were hexagonal.

XRD patterns showed the diffraction peaks due to titanium substrate and apatite in each condition (Fig. 3). It was also found that the diffraction peak corresponding to (002) of the apatite of the deposits had a higher intensity in comparison to the standard intensity, indicating an orientation to the c-axis direction of the apatite crystal. Therefore, it can be concluded that the needle-like crystal was a hydroxyapatite single crystal with <001> preferred orientation, indicating growth parallel to the c-axis direction.

Ca/P ratio of the deposits increased with the electrolyte temperature during deposition (Fig. 4). Ca/P ratios of the deposits at 90°C, 100°C, and 150°C were 1.38, 1.4, and 1.54 respectively, indicating a composition of Ca-deficient apatite. This is in agreement with a previous report12) on the Ca/P ratios of deposits on titanium plates.

Cell morphology

SEM observation showed that the morphology of cells attached on the apatite was flattened with numerous cytoplasmic extensions (Fig. 5). On the de-

Posited apatite at 150°C, cells were elongated with narrow cell projections.

Proliferation

Fig. 6 shows the absorbance directly corresponding to the number of osteoblast-like cells on the apatite-coated titanium mesh and without coating at 4, 8, and 12 days. For titanium mesh without coating, cell proliferation was displayed as 100% at 4 days. All substrates supported continuous cellular growth at 12 days. The number of adherent cells on the deposited apatite on titanium mesh was much greater than that on the surface without coating, and that it also depended on the morphology of apatites. At all time periods, cells proliferated actively and abundantly on the deposited apatite in the order of 150°C, 100°C, 90°C, and the titanium mesh without coating.

Differentiation

Fig. 7 shows the ALP activity of cultured osteoblast-like cells at 7 and 14 days. As for the apatite-coated titanium mesh at 90°C, it was significantly greater (p<0.05) than the control at 7 days. No differences in ALP activity were observed among the three types of deposited apatite specimens.

Fig. 8 shows the amount of collagen produced by cultured osteoblast-like cells on each specimen at 3, 9, and 15 days. Collagen production for all specimens decreased with incubation time. The apatite-coated mesh at 90°C and 100°C were significantly higher (p<0.05) than the control and the titanium mesh without coating at 3 days. No differences were observed in the collagen assay at 9 and 15 days.

Fig. 9 shows the osteocalcin assay of cultured osteoblast-like cells at 3, 9, and 15 days. The amounts of osteocalcin on all specimens increased with incubation time. The apatite-coated titanium mesh at 90°C and 100°C were significantly higher (p<0.05) than the control and the titanium mesh without coating at 15 days.

DISCUSSION

The results in the present study confirmed that apatites were homogeneously formed and oriented on the surface of the titanium mesh using hydrothermal-electrochemical method. Like the coating on a plate, it was shown in this study that the morphology and dimensions of the deposited apatite could be easily regulated by the electrolytic condition.

Cell culture test in the present study demonstrated that osteoblast-like cells attached well to the electrochemically deposited apatite, and that their morphology affected proliferation. For a barrier membrane (Guided Bone Regeneration), cell attachment to the material is essential because cell replication begins only after the cell has absorbed glycoproteins, established cell-substrate contact, and then adhered to and spread on the substrate. To allow these cellular events to occur, material used should have no deleterious effects on cell function. Furthermore, the material should possess the capacity to encourage cell spreading and proliferation. A key regulator of proliferation rate in anchorage-dependent cells is cell shape. Cells flattened with well-spread configuration divide at a higher rate than those which are rounded. SEM observation in the present study revealed that the attached cell on the electrochemically deposited apatite was flattened with numerous cytoplasmic extensions, and that no detrimental effects on cell development were observed.

Previous studies demonstrated that many factors govern the attachment of osteoblasts. One is the composition and surface topology of the substrate. Deligianni et al. reported that cell attachment was dependent on the surface roughness of hydroxyapatite. They found that the number of adherent cells per unit surface of apatite increased with the increase of surface roughness. In the present study, a greater number of cells adhered on the electrochemically deposited apatite on titanium mesh than on the surface without coating, as shown in Fig. 6. It seemed like cell adhesion was influenced by surface roughness — a result of deposited apatite on titanium mesh, as compared to the titanium mesh without coating. Indeed, this observation is augmented by a recent report that cells adhered more favorably to a sintered hydroxyapatite than to titanium due to a greater adsorption of adhesive ligands and integrins to the hydroxyapatite surface. Therefore, it can be concluded that the electrochemically apatite-coated titanium mesh provided for better cell adhesion. Wang et al. reported that owing to higher dissolution rate and relative rougher surface, carbonate apatite coating demonstrated the best goat bone marrow stromal cells attachment at 1 day and 3 days. In the present study, the number of adherent cells on the electrochemically apatite-coated titanium mesh at 150°C was much higher than on the other samples, although it exhibited a lower dissolution rate. This seemed to be caused by the wider surface area of (100) and (010) planes, which have relatively high dissolution. Furthermore, the difference in cell adhesion to biomaterials is known to depend on the composition or surface physicochemical properties. On this note, the difference in cell attachment according to the form and characteristics of apatite requires further research.

The remarkable result in this study was the higher cellular differentiation on the electrochemically apatite-coated titanium mesh than in the well

NII-Electronic Library Service
plate. It is well known that apatite enhances osteoblastic differentiation in vitro.\textsuperscript{36,29,32} Ozawa and Kasugai reported that ALP activity and the number of mineralized nodules on apatite produced by rat bone marrow stromal cells were higher than those on a culture plate or titanium.\textsuperscript{32} In addition, Hott et al. demonstrated that collagen synthesis and calcium uptake by human trabecular osteoblastic cells were higher on HAP than on plastic.\textsuperscript{30} With respect to cellular differentiation on apatite-coated titanium mesh versus that in cell culture plastic wells, our results obtained in this study were consistent with their results. The effect of surface roughness and composition of the extracellular matrix proteins, such as type I collagen and osteocalcin, when polystyrene and titanium were employed has been studied extensively.\textsuperscript{27,31,35,38} With respect to surface roughness, it was reported that increased surface roughness resulted in enhanced osteoblastic differentiation and production of matrix proteins, such as type I collagen and osteocalcin, when polystyrene and titanium were employed.\textsuperscript{27,31,35,38} In the present study, the electrochemically apatite-coated titanium mesh indicated higher measurement values than the titanium mesh without coating and that of the control in the early stage of the measurement of ALP activity and collagen of the extracellular matrix.

It is also known that the crystallinity degree of apatite influences osteoblastic differentiation.\textsuperscript{36,29,37} Morgan et al.\textsuperscript{36} reported that a significant inverse relationship was found for biologically mediated mineralization as a function of apatite crystallinity: low-crystalline surface had the highest level of mineralization, whereas high-crystalline surface yielded the lowest. Maxian et al.\textsuperscript{29} reported that gene expressions for osteocalcin, osteopontin, and ALP were enhanced by apatite with low crystallinity compared with high crystallinity in rat calvarial bone cell culture system. However, in this study, there were no significant differences in ALP activity among the three types of apatite specimens as shown in Fig. 7. Morgan et al.\textsuperscript{36} examined ALP activity at 72 hours, Maxian et al.\textsuperscript{29} did so at 2 days, while we examined ALP activity at 7 and 14 days in this study. It can therefore be concluded that there were significant differences in ALP activity between high-crystalline and low-crystalline surfaces in the early stages of proliferation.

These results demonstrated that the electrochemically apatite-coated titanium mesh showed good cell attachment and proliferation, and had a higher ability to enhance the differentiation of osteoblast-like cells than the titanium mesh without apatite coating. Furthermore, high-crystalline apatite such as the deposited apatite at 150℃ showed good cell attachment compared with the low-crystalline one, but high-crystalline apatite showed low differentiation when compared with the low-crystalline one. Ban et al. have reported on the pull-out bonding strength between rabbit femora and the titanium bars with and without the electrochemically deposited apatite coating at 100, 150, and 200℃ after three-week implantation.\textsuperscript{39} The pull-out bonding strength at 100℃ was the highest. This viewpoint may also relate to the higher biocompatibility of the electrochemically deposited apatite at 100℃ exhibited in this study, but further research is necessary in vivo.

Materials that are used for bone regeneration must provide good mechanical and digestive properties. However, it is very difficult to include these two different characteristics in one material. Sintered ceramics or metal materials have good mechanical strength and are useful for the reconstruction of bone\textsuperscript{29}, but they are not resorbed in the body. Some synthesized polymers or bipolymers have bioabsorbability but do not have sufficient strength.\textsuperscript{40-42} For these reasons, more than two materials of different characteristics have to be used to achieve ideal bone regeneration. The electrochemically apatite-coated titanium mesh developed in this study has two different characteristics, due to the differing properties rendered by apatite and titanium mesh.

These results suggested that the apatite-coated titanium mesh prepared by the hydrothermal-electrochemical method has an excellent bio-compatibility and it may be clinically applicable to guided bone regeneration.

CONCLUSION

With hydrothermal-electrochemical deposition method, apatites were homogeneously formed and oriented on the surface of titanium mesh. The cells attached and spread well on the deposited apatite on titanium mesh, whereby the number of adherent cells yielded was much greater than that on the surface without coating.

After measuring alkaline phosphatase activity as well as collagen and osteocalcin of the extracellular matrix, the electrochemically apatite-coated titanium mesh indicated higher measurement values than the titanium mesh without coating. These results suggested that the electrochemically apatite-coated titanium mesh has an excellent biocompatibility.
