(Received April 15, 2005)

Summary In this study, a dietary survey for 3 weekdays of young unmarried subjects [workers and students, 159 males and 160 females, ages 18–19 y (17.2%), 20–24 y (56.2%), 25–29 y (18.6%), 30–34 y (6.7%) and 35 y– (1.3%)] was performed. We evaluated the intake of green and yellow vegetables in this survey and determined the carotenoids ($\beta$-carotene, $\alpha$-carotene, lycopene, $\beta$-cryptoxanthin, and lutein+zeaxanthin) in 15 kinds of green and yellow vegetables frequently consumed. The carotenoid intake of each subject was calculated from the intake of these vegetables and the amount of carotenoid. Moreover, we studied the intake of protein, fat, and dietary fiber, and investigated its relationship to the intake of vegetables. The mean green and yellow vegetable intake/d in all subjects was 60.5 ± 58.7 g, much lower than the recommended level [120 g/d, (Health Japan 21 by Japanese Ministry of Health, Labour and Welfare)]. The intake of green and yellow vegetables was greater in females than males, and in workers than students. In all subjects, the mean total carotenoid intake/d was 2,852.8 ± 2,354.3 $\mu$g. In the total intake of carotenoids, there was no difference between males and females; however, the intake was greater in workers than in students. The intake of $\beta$-carotene and $\alpha$-carotene was greater in males than females. However, the intake of $\beta$-cryptoxanthin, lycopene, and lutein+zeaxanthin was greater in females than males. The group with the low green and yellow vegetable intake had not only a low carotenoid intake, but also a low intake of protein, fat, and dietary fiber. Therefore, it was suggested that carotenoid absorption may be affected by a low intake of protein, fat, and dietary fiber.

Key Words green and yellow vegetables, dietary carotenoid intake, carotenoid determination

Many young unmarried subjects eat neither breakfast, nor any green or yellow vegetables, which take a lot of time to prepare. Green and yellow vegetables are rich in carotenoids, such as $\beta$-carotene, and vitamin C, minerals, and dietary fiber. Moreover, in Japanese, about 56% of the vitamin A in diet comes from green and yellow vegetables (1). Green and yellow vegetable intake is still lower than that recommended by the Japanese Ministry of Health, Labour and Welfare (120 g/d, Health Japan 21). Therefore, we investigated the amounts and kinds of green and yellow vegetables consumed by young unmarried subjects.

One advantage of eating green and yellow vegetables is the intake of carotenoids. In recent years, carotenoids have attracted attention not only as a source of vitamin A, but also because of their reported contribution to antioxidation and inhibitory effects on cancer and various diseases (2–5). Therefore, it may be important to clarify the daily dietary carotenoid intake, and particularly, the differences in this intake among individual subjects. There are many reports (6–12) concerning carotenoid intake. However, the literature regarding the intake in young unmarried subjects is scant. We performed a dietary survey during 3 consecutive days, and clarified the kinds and amounts of green and yellow vegetables frequently consumed. We selected the top 15 green and yellow vegetables in terms of intake, and determined the amounts of carotenoids ($\beta$-carotene, $\alpha$-carotene, lycopene, $\beta$-cryptoxanthin and lutein+zeaxanthin) they contained. The carotenoid intake of each subject was calculated from the intake of the vegetables and the amounts of carotenoids.

Moreover, it has been reported that the absorption of carotenoids is affected by the amount of protein, fat, and dietary fiber (13–17) in a diet. It is suggested that the intake of protein, fat and dietary fiber differs among young subjects and may affect carotenoid absorption. We calculated the amounts of fat, protein, and dietary fiber taken in by individual subjects and investigated the relationship in terms of intake between carotenoid and protein, fat, and dietary fiber.

METHODS

1. Subjects and period of the survey. The subjects were 190 young unmarried workers (102 males and 88 females) and 129 students (57 males and 72 females)
Table 1. Daily intakes of energy, green and yellow vegetables and carotenoids in students and workers.

Energy intake and vegetable intake were calculated from the food intake survey. Carotenoid intake was calculated from the vegetable intake and the measured contents of carotenoids in the green and yellow vegetables frequently consumed.

Values are the mean±SD.

Values with different superscript letters are significantly different among males and females or among male students, female students, male workers and female workers (p<0.05).
and redissolved in 10 mL of n-hexane. The sample solution was used for high performance liquid chromatography (HPLC). For the analysis, HPLC was performed under the following conditions: column, Resolve C18 5 μm (150×3.9 mm ID) (Waters, Milford, MA, USA); mobile phase, acetonitrile : dichloromethane : methanol : water : 1-octanol : 10 : 5 : 0.15; column temperature, 30°C; flow rate, 0.8 mL/min; and detection wavelength, 451 nm.

4. Statistical analysis. Most values are shown as the mean±standard deviation. The mean value was compared between groups with a one-way analysis of variance, and differences were analyzed using Fisher’s least significant difference method; p<0.05 was regarded as significant. Moreover, the mean value was compared between males and females using Student’s t-test. The correlation between the intake of each nutrient and that of green and yellow vegetables was analyzed. Statistical processing was analyzed using “Excel Toki” (Social Survey Research Information, Japan).

RESULTS

1. Energy and green and yellow vegetable intake/d
As shown in Table 1, the energy intake was significantly larger in males (2,009.7±643.1 kcal/d) than females (1,862.9±433.0 kcal/d) (p<0.05). The mean green and yellow vegetable intake in all subjects was 60.5±58.7 g. The intake was greater in females (66.0 g/d) than in males (54.0 g/d), and the mean intake was greater in workers (65.1 g/d) than in students (52.5 g/d). Some 35.2% of males and 24.4% of females had very low intakes (<25 g/d). That is to say, the intake of vegetables was greater in females but the intake of energy was greater in males.

As shown in Table 2, in males, intake/d/subject was highest for tomatoes, followed in order by carrots and green sweet peppers. In females, the intake was highest for tomatoes, followed by carrots and then pumpkins. The mean intake/d of tomatoes was 25.6 g in the females and 17.7 g in the males, while that of carrots was 12.0 g and 15.6 g, respectively. The pumpkin intake in the females was 13.7 g, which was about 2.6 times that in the males.

In males, intake/d/subject was highest for tomatoes, followed in order by carrots, green sweet peppers, pumpkin, spinach, ha-negi, qing qin cai, pods, Chinese chive, broccoli, sweet peppers, okra, immature pods, asparagus, and komatsuna.

2. Analysis of carotenoid levels in green and yellow vegetables and carotenoid intake/d
An analysis of carotenoid levels in the top 15 green and yellow vegetables in terms of intake was performed to calculate the carotenoid intake of each subject. Lutein+zexanthin and β-carotene were detected in each type of vegetable as shown in Table 2. In addition, lycopene was detected in tomatoes, α-carotene in carrots, and β-cryptoxanthin in pumpkins. The lutein+zeaxanthin content was high in leafy vegetables.

Using these measurements and the intake of green and yellow vegetables, the amount of each carotenoid ingested was calculated (Table 1). In all subjects, total carotenoid intake/d was 2.852.8±2.354.3 μg, and the mean intake was 1.522.5±1.286.3 μg for β-carotene, 350.5±416.4 μg for lutein+zeaxanthin, 541.1±1,027.7 μg for lycopene, 424.5±440.4 μg for α-carotene, and 14.5±34.3 μg for β-cryptoxanthin. The intake of β-carotene and α-carotene was higher in males than females. It is thought that the intake of carrots, which contain large amounts of β-carotene and α-carotene, was greater in males than in females. On the other hand, the intake of lutein+zexanthin, lycopene, and β-cryptoxanthin was greater in females. In particular,
the intake of β-cryptoxanthin was significantly higher in females. Moreover, the intake of all carotenoids, lycopene, and lutein+zeaxanthin was greater in workers than in students. This may be because the intake of tomatoes was significantly higher in workers (25.3 g) than in students (16.3 g).

Though not shown in the figure, the distribution of total carotenoid intake/d was evaluated in males and females. Among males and females, the percentage of subjects with a total carotenoid intake of <2,000 µg/d was 45.9% and 45.3%, of 2,000–4,000 µg/d was 29.6% and 30.2%, of 4,000–6,000 µg/d was 15.7% and 13.9%, and of ≥6,000 µg/d was 8.8% and 10.6%, respectively.

3. Relationship between intake of green and yellow vegetables and intake of protein, fat, and dietary fiber

Effects of protein, fat, and dietary fiber on the absorption of carotenoids have been reported and so correlations between the intake of green and yellow vegetables and that of protein, fat, and dietary fiber were calculated, as shown in Fig. 1.

The coefficient of the correlation with protein, was 0.275 in males (p<0.01), and 0.536 in females (p<0.01). The subjects with a high intake of green and yellow vegetables had a high intake of protein, but the subjects with a low intake of these vegetables had a low intake of protein; therefore a low intake of protein may affect carotenoid absorption.

The coefficient of the correlation between the intake of green and yellow vegetables and that of fat, was 0.174 in males (p<0.05), and 0.223 in females (p<0.01), lower than that between the vegetables and protein or dietary fiber. However, subjects with a fat intake of <59 g/d (fat allowance×0.9) composed 80.4% of the male group with a green and yellow vegetable intake of <25 g/d, but 63.9% of that with a green and yellow vegetable intake of ≥75 g/d. Fat allowances were calculated according to Health Make Program ver. 4.0: Fat allowance (g)=energy allowance×0.23 (fat energy ratio)/9. In the females, the subjects with a fat intake of <46 g/d (fat allowance×0.9) accounted for 51.3% of the group with a green and yellow vegetable intake of <75 g/d, but 31.9% of the group with an intake of ≥75 g/d. Therefore, it was thought that the subjects with a high intake of green and yellow vegetables had a high intake of fat.

The coefficient of the correlation between the intake of green and yellow vegetables and that of dietary fiber was 0.328 in males (p<0.01), and 0.433 in females (p<0.01). Green and yellow vegetable are thought to contain much dietary fiber; therefore, the intake of dietary fiber correlated with the intake of these vegetables.

**DISCUSSION**

The intake of green and yellow vegetables was higher
in the 2002 National Nutrition Survey (88.5 g/d) (1) than in the 1993 survey (81.69 g/d) (19). However, it was still lower than the recommended intake (120 g/d, Health Japan 21), possibly due in part to a lack of understanding about the need for green and yellow vegetables in the young, including unmarried individuals. Kasamatsu (20) reported that the intake of these vegetables (68.5 g/d) in Wakayama Prefecture, where the present study was conducted, was much lower than the national average (81.69 g/d, 1993). The National Nutritional Survey in 1993 (19) reported a mean green and yellow vegetable intake of 57.0 g in subjects aged 20–29 y who live alone (54.0 g in males and 60.9 g in females), which was similar to the mean value for all subjects in the current study. Among the unmarried subjects of this study, the intake was lower in males than females. Moreover, it was lower in students than workers. The percentage of subjects taking in <57 g/d (average) of green and yellow vegetables was 59.6%, but the percentage of taking in >120 g/d (recommended intake) was 12.9%. The difference in the intake of green and yellow vegetables among subjects was great.

Carotenoid levels in 15 kinds of green and yellow vegetable were determined in order to calculate the intake of carotenoids. The amount of lutein+zeaxanthin in spinach has been reported to be 4.40 mg (21) or 9.89 mg/100 g (22) and that in broccoli, 0.80–2.44 mg (22–24), much higher than the values in this study. The β-carotene content of carrots has been reported to be 4.65–9.02 mg (22) or 7.60 mg/100 g (25), while that of spinach has been reported to be 3.30 mg (21) and 4.31 mg/100 g (25), similar to the values obtained here. However the amount of β-carotene in broccoli has been reported to be 0.78 mg/100 g (23) and that in asparagus, 0.49 mg/100 g (23), higher than the values in this study. On the other hand, the α-carotene content of carrots has been reported to be 0.53 mg (21), 3.06–4.89 mg (22), or 3.79 mg/100 g (25) and the lycopene content of tomatoes has been reported to be 3.10 mg/100 g (25), which were also close to the values in the present study. The variation may be explained by difference in the analytical methods used, the conditions and periods of cultivation, the length of storage, and the varieties in different countries and regions.

In this study, the intake was 2.852.8 μg/d for carotenoids overall, 1.522.5 μg/d for β-carotene, 350.5 μg/d for lutein+zeaxanthin, 541.1 μg/d for lycopene, 424.5 μg/d for α-carotene, and 14.5 μg/d for β-cryptoxanthin. It has been reported that in various foreign countries, the intake of carotenoids was 1.120–6.382 μg/d for β-carotene, 500–6,025 μg/d for lutein+zeaxanthin, 1.310–10,844 μg/d for lycopene, 527–1,174 μg/d for α-carotene, and 25–247 μg/d for β-cryptoxanthin (subjects aged 24–79 y) (6–9). Further, the following values were reported in Japan: 1.889–2,762 μg/d for β-carotene, and a mean intake of 181–306 μg for α-carotene and 1.731–3,326 μg for lycopene (subjects aged 40–69 y) (10–12). The intake of α-carotene and β-carotene in this study was similar to the mean from a previous study in Japan, but the lutein+zeaxanthin, lycopene, and β-cryptoxanthin intakes were lower than those reported previously. The amount of lycopene from processed tomato-based foods (ketchup and tomato juice) was added to the intake in this study. However, the levels of lycopene, lutein+zeaxanthin, and β-cryptoxanthin ingested were low. It is thought that less tomato, pumpkin, and spinach were consumed by the subjects in this study than in the previous study in Japan. However, there were few subjects with a high carotenoid intake in this study. The percentage of subjects with a total carotenoid intake of ≥6,000 μg/d was just 9.7%. It was clarified that the difference in carotenoid intake among the subjects was large.

The interaction between the consumption of green and yellow vegetables and the intake of fat, protein, or dietary fiber was analyzed in order to investigate the effect of the latter on the absorption of carotenoids. Figure 1 showed that subjects with a high intake of green and yellow vegetables have a high intake of protein and fat, and that subjects with a low intake of green and yellow vegetables have a low intake of protein and fat. It is reported that the amount of carotenoid absorbed was increased by adding fat (6–200 g) to basic meals (containing 60–137 g/d of fat) (13, 14). These studies were based on one test meal. Therefore, it is suggested that the absorption of carotenoids was influenced by the consecutive intake of fat and protein in the present study. There are reports that dietary fiber does (16, 17) and does not (15) affect the absorption of carotenoids. In the current study, the intake of dietary fiber was significantly greater in the group with a high intake of green and yellow vegetables (Fig. 1). The amount of carotenoid absorbed may be influenced by the intake of dietary fiber.

This study has several limitations. First, the intake of β-cryptoxanthin may have been seriously underestimated, because the major source of β-cryptoxanthin is citrus fruits. The carotenoids from fruit were not included in this study. Second, since the survey was only carried out in summer, the vegetables consumed were seasonal.

From the results of our analysis, the subjects who ate few green and yellow vegetables had small intakes of fat, protein, and dietary fiber. In contrast, those who ate many green and yellow vegetables had large intakes of fat, protein, and dietary fiber. Moreover, because the individual variation in the intake of green and yellow vegetables consumed was extensive, the variation in carotenoid intake from these vegetables was great. It is important that the effect of fat, protein, and dietary fiber on the absorption and metabolism of carotenoids be investigated, and that the influence of large or small amounts of these carotenoids on the health of subjects be clarified.
